Abstract: We herein report successful surgical treatment for a patient with infected traumatic pulmonary pseudocyst. A healthy 41-year-old male patient was transferred to our hospital due to traumatic head and chest injuries. On hospital day 9, follow-up computed tomography revealed infected pulmonary pseudocyst localized in right lower lobe. Despite of antibiotics administration, the patient did not recover from the infection. Therefore, surgical resection was planned. Right lower lobectomy was performed via posterolateral thoracotomy. The resected pulmonary pseudocyst contained frank pus caused by multidrug-resistance bacteria. The patient was transferred to other hospital for the rehabilitation after his general condition became stable.

Keywords: Surgical treatment; infection; traumatic pulmonary pseudocyst (TPP)

Introduction

Trauma can cause many patterns of thoracic injuries including rib fracture, hemopneumothorax, constitution, pseudocyst, major vessel injuries or diaphragmatic injuries.

Among them, traumatic pulmonary pseudocyst (TPPs) is relatively rare, and decreases in size and resolves completely without specific treatments such as surgery in most cases (1). Therefore, the outcome of TPP is considered favorable when the patient has no other accompanied traumatic injuries.

Ulutas and colleagues reported that only 1 of 52 patients with TPP, which was enlarged up to 15 cm progressively, required surgical treatment (1).

Cho and colleagues also reported that there were no TPPs among 81 cases receiving additional invasive treatments after closed thoracostomy because none of them did not have any complications such as massive hemoptyis or infected TPP (2). However, surgical treatments can be required if the patient with TPP suffers from such complications because these complications can be life-threatening.

Here we report a successful surgical result of infected TPP, and review relevant literatures.

Case presentation

A healthy 41-year-old male patient was transferred to our hospital by a medical helicopter due to traumatic head and chest injuries. An initial computed tomography (CT) on admission revealed acute subdural hematoma and pulmonary congestion. Mechanical ventilation was introduced to keep respiratory status, however, he suffered from pneumonia as a result. Therefore, antibiotics were administered to treat the pneumonia. On hospital day 9, follow-up CT revealed emergence of infected pulmonary pseudocyst localized in right lower lobe (Figure 1). Although antibiotics administration was continued, the patient did not recover from the infection. Therefore, surgical resection of infected TPP was planned to control the infection.

Under general anesthesia, posterolateral thoracotomy was performed on decubitus position. We did not choose thoracoscopic approach because lung swelling due to congestion was expected to prevent us from getting good
and we were not able to insert staplers in order to incise intersegmental plane because of lung swelling due to severe pulmonary congestion. Therefore, conventional right lower lobectomy was performed. The resected pulmonary pseudocyst contained frank pus containing multidrug-resistance bacteria in the cavity (Figure 2). Bronchial stump was wrapped by a flap of intercostal muscle.

The patient gradually recovered after removal of chest drainage tube on postoperative day 2, and was finally transferred to other hospital for the sake of rehabilitation.

**Discussion**

Thoracic surgeons or physicians sometimes treat TPP clinically although TPP is relatively rare disease among chest trauma. It is considered that TPP results from laceration or tearing of lung parenchyma, and air can enter through the laceration and create a cavity when a laceration causes only minor vascular damage and does not communicate with the pleural space. Subsequently, the air becomes trapped and the resulting cyst has no epithelial lining. As a result, connective tissue forms the lesion’s wall. Although most previous reports described TPP is caused by severe blunt trauma as well as our case, Ulutas et al. insisted that penetrating trauma also can cause TPP because the result in their article revealed there was no significant difference between the proportion of blunt trauma patients who developed TPP and the proportion of penetrating trauma patients who developed TPP (1).

TPP usually regresses spontaneously with conservative treatment (1,2). However, TPP may be treated if the patient has some complications such as hemothorax, pneumothorax, massive hemoptyisis, or infection (3,4). Several authors reported infected TPPs which received additional surgical treatments, however, most of the literatures were written several decades ago (4,5). We speculate that recent advancement of antibiotic therapy can avoid progression of infection in most patients with TPPs. However, infected TPP sometimes becomes fatal when treated by only antibiotics administration. Carroll et al. reported that 4 patients with infected TPPs remained septic for weeks despite appropriate antibiotic therapy (4). While one of the four patients finally died of the infectious process, one patient successfully recovered after surgical treatment. The remaining 2 patients recovered from infection with antibiotics treatment alone, however, the course was prolonged. Our patient also did not recover from infection in spite of appropriate antibiotics administration. Therefore,
we decided to perform surgical resection of TPP and finally got a successful result, suggesting the necessity of additional invasive treatments including surgery for infected TPP.

Gincherman and colleagues reported the successful results of CT-guided catheter drainage for a TPP instead of surgical resection of TPP (6). We performed surgical resection under general anesthesia because it was considered more radical. However, other less invasive treatments might be appropriate when the general condition is unstable due to injuries of other parts caused by trauma. Additionally, there are no reports describing appropriate surgical procedures to our best knowledge. In most previous reports, thoracotomy approach was chosen because these articles were written several decades ago (4,5). In our case, lung swelling caused by severe pulmonary congestion was expected to prevent us from getting good surgical viewing, and thoracoscopic approach gives surgeons limited surgical viewing. Therefore, we did not choose thoracoscopic approach.

Conclusions

We experienced a successful surgical result of infected TPP. Although TPP is relatively rare disease among chest trauma and usually regresses spontaneously with conservative treatment, TPP may be treated if the patient has some complications such as hemothorax, pneumothorax, massive hemoptysis, or infection. Therefore, we should keep the necessity of surgical treatment in mind when we encounter the patients with TPP.
